

II. HEARING:

- ❖ the perception of sound and equilibrium
- ❖ takes place in the ears

A. Anatomy of the Ear:

1. External Ear:

- a. **Auricle** – funnels sound waves toward the inner ear (ear lobe)
- b. **External auditory canal** – tube that extends through the temporal bone to the inner ear; lined with hair and **cerumen** (wax) to keep out foreign materials; opening is the **external auditory meatus**

- c. **Tympanic membrane** –sound waves bounce off this thin barrier, creating vibrations (ear drum)

2. Middle Ear:

- a. **Auditory Ossicles** – carry vibrations from the tympanic membrane; smallest bones in the body
- **malleus** – transfers vibrations from the tympanic membrane to incus
 - **incus** – transfers vibrations to the stapes
 - **stapes** – transfers vibrations to the inner ear

- b. **Eustachian tube** – pathway that connects the middle ear to the pharynx; maintains air pressure on both sides of the tympanic membrane

3. Inner Ear (imbedded in the temporal bone):

- a. **Vestibule** – the region between the semicircular loops and the cochlea (contains the **oval window**)
- b. **Cochlea** – spiral structure that receives sound waves; contains the **organ of Corti** which converts sound vibrations into nerve impulses
- c. **Semicircular canals** – 3 fluid-filled loops that helps sense equilibrium/balance

B. The Physiology of Hearing:

1. **auricle** funnels sound waves through the **external auditory meatus** into the **external auditory canal** which cause the **tympanic membrane** to vibrate
2. the vibrations move through the **auditory ossicles** (MIS)
3. movement of the stapes, which is connected to the **oval window** of the **vestibule** sends vibrations through the **cochlea**
4. the vibrations stimulate the **Organ of Corti** to send a nerve impulse **cochlear nerve** to the brain for processing
5. sound waves leave the cochlea and exit through the **eustachian tube**
